Modern ray-finned fishes (Actinopterygii) comprise half of extant vertebrate species and are widely thought to have originated before or near the end of the Middle Devonian (~385 million years (Myr) ago)¹⁻⁴. Polypterids (bichirs and ropecfish) represent the earliest-diverging lineage of living actinopterygians, with almost all Palaeozoic taxa interpreted as more closely related to other extant actinopterygians than to polypterids⁵⁻¹⁰. By contrast, the earliest material

assigned to the polypterid lineage is mid-Cretaceous (ca. 100 Mya) in age¹¹, implying a quarter-of-a-billion-year palaeontological gap. We show that scanilepiforms, a widely distributed Triassic (ca. 252-201 Mya) radiation, are stem polypterids. Significantly, these fossils break the long polypterid branch and expose many supposedly primitive features of extant polypterids as reversals. This shifts numerous Palaeozoic ray-fins to the actinopterygian stem, reducing the minimum age for the crown lineage by roughly 45 Myr. Recalibration of molecular clocks to exclude phylogenetically reassigned Palaeozoic taxa results in age estimates for the actinopterygian crown lineage ~20–40 million years younger than previous molecular analyses¹⁻⁴. These new dates are broadly consistent with our revised palaeontological timescale and coincident with an interval of conspicuous morphological and taxonomic diversification among ray-fins centred on the Devonian-Carboniferous boundary¹²⁻¹⁴. A shifting timescale, combined with ambiguity in the relationships of late Palaeozoic actinopterygians, highlights this part of the fossil record as a major frontier in understanding the evolutionary assembly of modern vertebrate diversity.

The roughly dozen living species of polypterids have long vexed vertebrate biologists¹⁵. These freshwater, African endemics were only recognized as ray-finned fishes in the early 20th century^{16,17}, although this view was resisted by some until the 1970s¹⁸. Anatomical and molecular data now support placement of polypterids as the living sister group of all other extant actinopterygians^{1-7,9,19}. Morphological analyses generally resolve polypterids as one of the earliest diverging ray-finned lineages, with only the Middle-Late Devonian *Cheirolepis* consistently falling on the

actinopterygian stem^{5-7,9,20}. Despite apparently ancient evolutionary origins and perceived status as ‘living fossils’¹⁵, polypterids have a meagre palaeontological record consisting largely of fragments^{10,11}. The oldest polypterids are mid-Cretaceous in age²¹, postdating the predicted origin of the lineage by at least 285 Myr, and show few differences from modern species^{17,22,23}, which originated in the Miocene (ca. 20 Myr¹⁵). The lack of specializations found in early representatives of other living ray-fin groups suggests an ancient origin for polypterids, but several of these absences concern distinctive aspects of polypterid morphology that do not closely resemble the anatomy of the oldest ray-finned fishes^{10,15}. Fossils have played an important role in establishing relationships among living actinopterygian lineages^{16,19}, so the lack of early polypterids leaves an outstanding gap in our understanding of the evolutionary history of this group and of vertebrates more generally.

Scanilepiformes is a widespread group of Triassic ‘palaeoniscoid’ fishes known from continental or marginal marine deposits in Sweden, Russia, China, Kyrgyzstan and the United States. Links between scanilepiforms and polypterids have been made based on morphological similarity, referencing a mix of ancestral (e.g., large gular plates) and derived, but homoplastic (e.g., long-based dorsal fin), characters²⁴⁻²⁵. However, past cladistic analyses resolve scanilepiforms as actinopterygians, specifically stem-group neopterygians^{9,26}, rejecting a close phylogenetic relationship with polypterids.

Most scanilepiform fossils are heavily compressed, limiting investigations to external anatomy. The Middle Triassic *Fukangichthys* represents an important exception (Fig. 1, Extended Data Figures 1–3). High-resolution micro-computed tomography (μCT)

of three-dimensionally preserved skulls illuminates internal cranial anatomy of scanilepiforms. The trough-shaped interorbital walls, which do not contact at the midline (Fig. 1c and Extended Data Figure 1c), are separated from the weakly ossified otic and occipital regions of the neurocranium (Extended Data Figure 1a). The optic foramen is ventrally positioned, and the parasphenoid contributes to its lower margin (Fig. 1b,c and Extended Data Figure 1b,c). The parasphenoid has long but simple ascending processes, a triangular corpus pierced by a hypophysial canal, and no posterior stalk (Fig. 1b,e and Extended Data Figure 1b,e). A small median vomer lies anterior to the parasphenoid (Fig. 1e and Extended Data Figure 1e). Dermal bones on the inner surface of the palate include the accessory vomer, dermetapterygoid, three dermopalatines, entopterygoid, and an ectopterygoid bearing a lateral process that articulates with the inner face of the maxilla (Fig. 1e and Extended Data Figures 1e, 4). Like the maxilla and premaxilla, the dentary bears a single row of peg-like teeth. The hook-shaped coronoid process is composed exclusively of the prearticular (Fig. 1b and Extended Data Figures 1a, 4e). A modest opercular process extends from the ‘L’-shaped hyomandibula, which is imperforate and unfused to the dermohyal (Fig. 1b and Extended Data Figure 1b). Plate-like ceratohyals, which bear a groove for the afferent hyoid artery, flank the four pairs of ceratobranchials and hypobranchials (Fig. 1d and Extended Data Figures 1d, 5). Epibranchials bear uncinate processes, and multiple basibranchial ossifications may be present (Fig. 1d and Extended Data Figures 1d, 5).

We conducted a revised analysis of actinopterygian interrelationships based on an expanded morphological dataset²⁷ (93 taxa, 265 characters), and an analysis of this morphological dataset combined with DNA sequences of 12 nuclear genes.

Phylogenies were inferred using both parsimony (Fig. 2 and Extended Data Figures 6, 7) and Bayesian methods (Extended Data Figure 8). In contrast to some, but not all²⁸⁻²⁹, previous studies, we have rooted our analyses on a set of non-actinopterygian outgroups, rather than *Cheirolepis*^{6,9,26} or a hypothetical ancestor^{7,20}. With respect to living actinopterygians alone, we corroborate the placement of chondrosteans and polypterids as successively more remote outgroups to neopterygians (Fig. 2 and Extended Data Figures 6–8)^{1-10,26,28}, although this resolution is lost in phylogenies inferred by Bayesian analysis of morphological data (Extended Data Figure 8B). With respect to fossil taxa alone, our results are congruent with previous studies: an early diverging assemblage of Devonian taxa, a grade of ‘palaeoniscoid’ lineages arising in the later Palaeozoic, and a series of early Mesozoic ‘subholostean’ taxa branching immediately outside of crown Neopterygii^{1,6-7,9,26}.

Where our results differ substantially from the generally accepted pattern of actinopterygian diversification is in the intersection of relationships between living and fossil taxa. Polypterids are nested within scanilepiforms, and numerous Devonian–Triassic taxa previously interpreted as crown actinopterygians are resolved as stem-lineage ray-finned fishes. Consequently, a late Middle or early Late Devonian (ca. 385–378 Ma;^{1,5-7,9}) minimum for the actinopterygian crown is not supported (successive nodes excluding Devonian taxa from crown: BPPs in morphology analysis = 0.83, 0.69; BPPs in combined analysis = 0.96, 0.83; Bremer decay indices = 2, 2, 4, 2). The crown node is subtended by a polytomy in the Bayesian analyses, creating ambiguity as to a revised minimum age of actinopterygians. However, no resolution is compatible with a minimum older than Viséan, some 45 million years younger than currently held^{1-4,30}.

126

127 The monophyly of polypterids plus scanilepiforms is strongly supported (BPP = 0.98-
128 0.92; Bremer decay index = 4) and rests on features distributed throughout the
129 skeleton, including: optic foramen adjacent to dorsal margin of parasphenoid; broad
130 interorbital septum; lateral process of the ectopterygoid¹⁹; four ceratobranchials³¹; loss
131 of fulcra along dorsal ridge of caudal fin; and coronoid process of the lower jaw
132 composed exclusively of the prearticular (Supplementary Information and
133 Supplementary Figure 1).

134

135 This revised placement of scanilepiforms indicates that many apparently primitive
136 features of polypterids are reversals. These include traits also absent in other living
137 actinopterygian lineages, but long recognized as parallel losses through identification
138 of early fossil members of those groups: fringing fulcra (retained only by gars), a
139 surangular (retained only by holosteans), a spiracular canal (retained only by
140 chondrosteans and holosteans), and a lateral cranial canal (retained only by
141 chondrosteans and gars). We note that the cranial endocavity of *Erpetoichthys* bears
142 short lateral diverticulae aligned with the posterior semicircular canal, possibly
143 representing a vestigial lateral cranial canal (Extended Data Figure 9). Additional
144 features previously cited as evidence for an especially deep divergence of polypterids
145 within actinopterygian phylogeny do not closely match either generalised
146 osteichthyan or derived actinopteran conditions, but in fact are best described as a
147 third, probably autapomorphic, state. This is particularly apparent in the pectoral-fin
148 skeleton of polypterids, which is coded identically to that of *Cheirolepis* in many
149 analyses^{6-7,9}, but which shows a highly specialized architecture¹⁸.

150

Revised paleontological minima for deep actinopterygian divergences could alter the inferred timeline of actinopterygian evolution^{1-4,10}. To assess the temporal implications of new fossil placements, we conducted two parallel relaxed molecular clock analyses. We utilized previously proposed paleontological constraints^{2,4,31}, but varied application of actinopterygian calibrations of Palaeozoic and earliest Mesozoic ages. The first analysis employed constraints in line with past interpretations of early actinopterygian phylogeny¹⁻⁴. Our second analysis excluded these calibrations entirely, relying on well-established minima for outgroups and nested ray-fin clades to estimate the timing of early actinopterygian divergences via interpolation. We have not assigned new calibrations to these deep nodes for three reasons. First, a lack of consistent resolution across our trees hinders the identification of specific minima. Second, phylogenetic leaf stability of Carboniferous-Early Triassic actinopterygians is substantially lower than that of either stratigraphically earlier or later forms (Fig. 3; although scanilepiforms are relatively stable). When adjusted for taxonomic incompleteness, Early Triassic taxa perform particularly poorly (Fig. 3b). The variable positions of many Carboniferous-Early Triassic taxa across the actinopteran, neopterygian and chondrosteian stems in our analyses (Extended Data Figures 6 and 8) questions the reliable identification of calibrations at present. Third, and most significantly, interpolated—as opposed to directly calibrated—node-age estimates for these deep divergences provide an independent assessment of the two competing age models for the actinopterygian crown clade: evolution deep within the Devonian, or a later origin in the Carboniferous as suggested by our new phylogenetic results.

The two analyses deliver largely non-overlapping ages for the actinopterygian crown node (Supplementary Table 1): use of all calibrations results in a late Emsian-earliest

Frasnian estimate (mean: 389.9 Ma [Eifelian]; 95% HPD: 382.6, 397.8 Ma), while the restricted calibration set yields a much younger estimate, latest Givetian-Viséan (mean: 359.6 Ma [terminal Famennian]; 95% HPD: 335.5-384.1 Ma). This younger age estimate cannot reject crown-group membership for the Devonian *Mimipiscis* and *Moythomasia*³⁰ on temporal grounds, but they lie far within the oldest tail of the posterior age distribution. By contrast, this molecular age estimate closely matches a first palaeontological appearance of crown lineage actinopterygians in the Mississippian, even though these fossils were not used as calibrations in the relaxed molecular clock analyses. The divergence between mean age estimates under these two calibration strategies differs by approximately 30 Myr, corresponding roughly to the difference between palaeontological minima for the actinopterygian crown indicated by past studies²⁻³ and our own results. Our revised timescale places the origin of the modern ray-finned fishes near the Devonian-Carboniferous boundary, after which considerable taxonomic and morphological diversification is apparent in the actinopterygian fossil record^{8,10,12-14}. This supports an emerging view of the early Carboniferous as a critical interval in establishment of key modern vertebrate radiations.

361 kV microCT (developed by the Institute of High Energy Physics, CAS) at the
362 following parameters: 150 kV, 100 μ A, 720 projections, with a voxel size of 14.9 μ A.
363 *Erpetoichthys calabaricus* BMNH 2016.9.22.3 was scanned at King's College
364 London with a voxel size of 8 μ m. After scanning, data were segmented in Mimics
365 (biomedical.materialise.com/mimics; Materialise, Leuven, Belgium). Surface meshes
366 were then exported into and imaged in Blender (blender.org; Stitching Blender
367 Foundation, Amsterdam, the Netherlands).

368

369 **Phylogenetic analyses.** Analyses were performed in PAUP* 4.01150³² and MrBayes
370 v.3.2.6³³. The morphological-only dataset is based on ref. 27, but heavily expanded to
371 incorporate additional Palaeozoic, Mesozoic and Recent taxa, as well as additional
372 characters (both novel and drawn from the literature; see Character List for full
373 references) with a bearing on their relationships. The resultant dataset comprises 265
374 characters and 93 taxa, and was analysed in PAUP* and MrBayes. A combined
375 morphological and molecular dataset (with DNA sequences of 12 nuclear genes; only
376 eight sampled for *Atractosteus*) was also analysed in MrBayes. Non-osteichthyan taxa
377 were used in the outgroup and enforced with a constraint tree:

378 [*Dicksonosteus*[*Entelognathus*[*Acanthodes*, *Cladodoides*, *Ozarcus*[ingroup]]]]. A

379 small number of characters and incomplete taxa were excluded from the matrix of ref.
380 27. We assessed taxonomic equivalence³⁴ using Claddis³⁵, with no taxa found to be
381 equivalent. Of the ten taxa coded for both morphological and molecular data in the

combined analysis, six are composites of more than one species, with three (two of which are constrained in the outgroup, and one of which is a sarcopterygian) coded from more than one genus, as follows: morphological data: *Cladodoides wildungesis*, molecular data: *Leucoraja erinacea*; morphological data: *Ozarcus mapesae*, molecular data: *Callorhinchus milli*; morphological data: *Miguashaia bureau*, molecular data: *Latimeria chalumnae*; morphological data: *Polypterus bichir*, molecular data: *Polypterus senegalus*; morphological data: *Acipenser brevirostrum*, molecular data: *Acipenser fulvescens*; morphological data: *Elops hawaiiensis*, molecular data: *Elops saurus*; *Erpetoichthys calabaricus*, *Lepisosteus osseus*, *Hiodon alosoides* and *Amia calva* coded for both morphological and molecular data.

An equally weighted parsimony analysis in PAUP was conducted with 500 random addition sequences, five trees held at each step, maxtrees set to automatically increase, nchuck= 10 000, chuckscore= 1, and TBR enabled. Bootstrap values were calculated in PAUP using 500 replicates of a heuristic search, with five trees held at each step, rearrlimit= 50 000 000, limitperrep= yes, nchuck= 10 000, chuckscore= 1. Bremer Decay values were calculated in PAUP.

Bayesian analyses was run under the *Mkv* model. Each dataset (i.e. combined morphology and molecular and morphology only) was run until the standard deviation of split frequencies reached less than 0.01, indicating convergence had been reached, and this was confirmed in Tracer³⁶. The first half of each run was discarded as burn-in.

Leaf stability. Leaf stability was calculated using RogueNaRok³⁷, which utilises trees generated during bootstrapping. Due to the computational limitations of RogueNaRok, the 2554771 bootstrap trees were downsampled: random subsamples of 30 trees were generated using R³⁸, with maximum leaf stability then calculated for the subset using the package ape³⁹. This process was repeated ten times, with the average maximum leaf stability plotted using the package geoscale⁴⁰ (Fig. 3a) and standard deviation used as error (Extended Data Figure 10b). It may be expected that more completely coded taxa will have higher leaf stability values by virtue of having lower levels of anatomical uncertainty. To counter this, maximum leaf stability was corrected for taxonomic incompleteness by calculating the residuals of a linear regression between completeness and stability (Figure 3b, Extended Data Figure 10c). The moving average was calculated by separating taxa (using midpoint of stage age) into 25 Myr bins and calculating the average over two consecutive bins.

Divergence estimates. Divergence times of the sampled osteichthyan lineages were estimated using the random local clock (RLC) model of molecular evolutionary rate heterogeneity implemented in the computer program BEAST v. 1.8.1^{41–43}. The nucleotide substitution models were partitioned by gene and codon position for the 12 nuclear gene dataset, as in the MrBayes analysis above. A total of eighteen exponential calibration priors from the fossil record of osteichthyans and chondrichthyans were identified in the RLC analyses. As described in the text, the first divergence time analysis used all calibrations, while the second held all aspects of the analysis constant except for censoring all Palaeozoic-Triassic actinopterygian calibrations. A birth-death speciation prior was used for branching rates in the phylogeny. The BEAST analyses were run ten times and were combined using the

computer program LogCombiner v. 1.8.1 (<http://beast.bio.ed.ac.uk/LogCombiner>).
Convergence of model parameter values and estimated node-heights to their optimal
posterior distributions was assessed by plotting the marginal posterior probabilities
versus the generation state in Tracer v. 1.6. Effective sample size (ESS) values were
calculated for each parameter to ensure adequate mixing of the MCMC (ESS>200).
The posterior probability density of the combined tree and log files was summarized
as a maximum clade credibility tree using TreeAnnotator v. 1.8.1
(<http://beast.bio.ed.ac.uk/TreeAnnotator>). The mean and 95% highest posterior
density estimates of divergence times and the posterior probabilities of inferred clades
were visualized on the using the computer program FigTree v. 1.4.0
(<http://beast.bio.ed.ac.uk/FigTree>).
